The oldest known riffle beetle (Coleoptera: Elmidae) from Early Cretaceous Spanish amber

Le plus ancien Coléoptère Elmidae dans l’ambre du Crétacé inférieur d’Espagne

A B S T R A C T

Elmadulescens rugosus Peris, Maier et Sánchez-García n. gen. n. sp. is described based on a single specimen from Spanish amber (El Soplao outcrop, Early Albian, Early Cretaceous). The discovery of this specimen in amber is very interesting, since aquatic beetles are not common in fossil tree resin. This fossil pushes back the oldest known specimen of Elmidae from the Eocene (~40 Ma) to at least the Early Cretaceous (~110 Ma).

R É S U M É

Elmadulescens rugosus Peris, Maier et Sánchez-García n. gen. n. sp. est décrit d’après un spécimen unique d’ambre d’Espagne (gisement d’El Soplao, Albien inférieur, Crétacé inférieur). La découverte de ce spécimen dans l’ambre est notable, puisque les coléoptères aquatiques sont rares dans la résine végétale fossile. Le registre fossile des Elmidae est ainsi repoussé de l’Eocène (~40 Ma) jusqu’au Crétacé inférieur (~110 Ma).

1. Introduction

Coleoptera comprises roughly a quarter of all recently described animal and plant species, making them the primary contributor to Earth’s biodiversity and the most prolific order of insects (Beutel and Haas, 2000; Hunt et al., 2007). Among the beetles, the transition to a life in water has occurred several times. Thirty beetle families have aquatic representatives and in at least 25, the majority of species are considered aquatic (Jäch and Balke, 2008). Major radiations have evolved in the Noteridae Thomson and Dytiscidae Leach in Adepagha and the Hydrophilidae and Byrrhoidae in Polyphaga (Kodada and Jách, 2005a; Ribera et al., 2002).

The Elmidae Curtis (suborder Polyphaga), commonly known as the “riffle beetles”, are one of the important radiations of aquatic Byrrhoidae, found in a variety of running water habitats throughout the world. The family includes more than 1300 species, but the phylogeny for the family and for the Byrrhoidae is still lacking (Čiampor and Čiamporová-Zat'ovičová, 2008; Jäch and Balke, 2008). The Elmidae is divided into subfamilies Larainae LeConte and Elminae Curtis (Kodada and Jách, 2005a). Although elms are considered aquatic beetles, only species of the subfamily Elminae can be regarded as “true water beetles” since they complete nearly their entire life cycle in water (Jách, 1998). Adults of the subfamily Elminae live and feed underwater while the Larainae are considered strictly aquatic only as larvae (Brown, 1987). Adult elmines emerge following pupal eclosion and take their only dispersal flight; this flight can take several days out of the water (Seagle, 1980).

Brown (1987) hypothesized the antiquity of the elms based on the geographical distribution of extant forms. Under the present understanding of continental drift, he predicted the probable origin of the family before Cretaceous. Despite their theoretical antiquity and their common aquatic habitat, the fossil record of this family is very scarce. Kodada and Jách (2005a) and Kirejshuk and Ponomarenko (2014) summarized the fossil record, which consists of some fossils from glacial and post-glacial deposits very similar to extant species (Brown, 1987) and Palaeorohelmis samlandica Bollow from the Eocene Baltic amber. P. samlandica bears similarity to the extant genera Riolus Mulsant et Rey and Limnius Illiger, and was the oldest elmid fossil known (approximately 40 Ma) (Bollow, 1940; Wichard et al., 2009).

The aim of this work is to provide evidence for the oldest known fossil riffle beetle, collected from Early Cretaceous amber from Spain. With this evidence, the origin of elms at least before 110 Ma is confirmed.

Institutional abbreviations. CES—El Soplao collection in El Soplao cave, Celis, Cantabria, Spain.

Other abbreviations. Ma—millions of years ago.

2. Outcrop and geological setting

The El Soplao site is one of the most important Cretaceous amber deposits from Spain. Together with the Peñacerrada I and the San Just sites (the three most intensively studied amber deposits), and some other less studied localities, the Spanish Cretaceous amber is found in outcrops distributed in a narrow arc from eastern to northern Iberian Peninsula (Peñalver and Delclòs, 2010). This capricious distribution is coincident with the north marine coastline of the Iberian plate during the Early Cretaceous (fig. 2 in Peñalver and Delclòs, 2010).

The El Soplao site is Early Albian from the western part of the Basque-Cantabrian Basin (northern Spain). The amber-bearing deposit occurs in a non-marine to transitional marine silicilastic unit (Las Peñosas Formation), in a deltaic-estuarine environment developed in the regressive stage of a regressive-transgressive cycle (Najarro et al., 2009, 2010).

The amber pieces were found in a level of organic-rich clays 0.7–2.5 m thick, along with dinoflagellates, spores of vascular cryptogams, pollen grains of gymnosperms and angiosperms, abundant gymnosperm plant cuticle remains, charcoal, and marine or brackish-water invertebrates, such as gastropods and bivalves. The presence of serpulids and bryozoans as epibionts, on the surface of some amber pieces (originally epibionts of the resin masses), indicates both a littoral to coastal marsh palaeoenvironment and a mixed assemblage of resin deposit (Najarro et al., 2010; Peñalver and Delclòs, 2010).

To date, this amber deposit has yielded 649 arthropod bio-inclusions belonging to Arachnida (Acariformes), Crustacea (Order Tanaidacea) and Hexapoda in 14 recognized orders: Collemboidea, Blattaria, Isoptera, Pscooptera, Thysanoptera, Raphidoptera, Neuroptera, Hemiptera, Coleoptera, Trichoptera, Lepidoptera, Hymenoptera, Mecoptera, and Diptera (Pérez-de-la Fuente, 2012).

3. Materials and methods

The sample described in this paper is CES–567; no other syninclusion is found with it. This fragile piece of amber was cut and embedded in a transparent epoxy resin, following the process described in Nascimbene and Silverstein (2000).

The specimen reported in this paper was examined under three different lenses, i.e., a Leica M55 stereomicroscope, and a Motic BA310 and an Olympus BX41 compound microscopes with reflected and transmitted light. Photomicrographs were made with a Canon EOS 7D digital camera attached to an Infinity K-2 long distance microscope lens for general habitus, and a MOTICAM 2500 camera attached to the Motic BA310 compound microscope for lateral habitus and details. All of them were arranged and sharpened with CombineZP (Hadley, 2010) and edited with Photoshop Elements 10 and CorelDraw X6. Illustrations were prepared with the aid of a camera lucida attached to an Olympus BX41 compound microscope.

Terminology in the description follows that used in Lawrence et al. (2000) and characters used for the placement of the genus follow Shepard (2002) and Kodada and Jách (2005a). The family classification is from Bouchard et al. (2011).
4. Systematic palaeontology

Order COLEOPTERA Linnaeus, 1758
Suborder POLYPHAGA Emery, 1886
Superfamily BYRRHOIDEA Latreille, 1804
Family ELMIDAE Curtis, 1830
Subfamily incertae sedis
Genus Elmadulescens Peris, Maier et Sánchez-García n. gen.

Figs. 1 and 2

Derivation of name. The generic name is the combination of Elm – from Elmidae and – adulescens from the Latin of “young”. The suffix was chosen because it is the oldest fossil Elmidae, so the youngest in classification.

Type species. Elmadulescens rugosus Peris, Maier et Sánchez-García n. sp.

Diagnosis. Dorsal body surface covered with long, and evenly dispersed setae; antennae with last three antennomeres slightly wider than the preceding antennomeres; pronotum with strong sublateral carinae, without transverse or longitudinal depressions or grooves; dorsal surface strongly punctuate and wrinkled, elytral punctures organized in longitudinal rows, intervals very sclerotized and slightly convex near base; edge of the pronotum and elytron thickened, bearing a row of erect, long setae.

Description. Body elongate, subparallel, moderately convex (Figs. 1A, 2A). Dorsal surface covered with long and disperse erect setae; setae narrowed and acute apically, hair-like.

Head deflexed, slightly retracted into prothorax (Fig. 2A). Eyes strongly protubерant and coarsely faceted, separated by a distance equal to the width of eye (Fig. 1A). Antennae long, filiform, with more than nine antennomeres (only nine are visible in the specimen, there are likely eleven antennomeres) (Fig. 2D); antennal insertions widely separated, inserted at the level of the eyes; scape slightly longer than pedicel.

Pronotum quadrate, 1.5 times wider than head; surface deeply punctured; disc of pronotum with two longitudinal sublateral carinae, lacking obvious depressions or grooves; surface strongly wrinkled; lateral borders of pronotum subparallel, slightly convergent near apex (Fig. 1A). Prosternum moderately long in front of procoxae, about as long as procoxae; prosternal process long, moderately narrow, subparallel, with rounded apex. Scutellum pentagonal, about as wide as long. Metaventrite long, approximately twice the length of the first abdominal ventrite (Fig. 1B).

Elytra deeply punctuate; without sublateral carinae; elytral surface apparently without grooves or depressions, but strongly wrinkled (Fig. 1A). Elytral humeri with strong and distinctly protubерant carinae.

Procoxae globular, enlarged, and separated by at least half the width of coxa. Mesocoxae globular and separated by width of coxa; metacoxae transverse, not reaching edge of metasternum; metacoxae narrowly separated; meta-coxae with distinct posterior face, excavated posteriorly for reception of metafemora in reposito; metatrochanter triangular.

Legs long, femora and tibiae slender; tibiae covered with short setae laterally. Tarsal formula 5–5–5. Tarsi loose, simple, roughly same length as tibiae; apical tarsomeres nearly as long as preceding four tarsomeres combined (Fig. 2C). Tarsal claws long, robust, apparently lacking teeth.

Abdomen with five ventrites. Ventrite I slightly longer than remaining four ventrites.

Elmadulescens rugosus Peris, Maier et Sánchez-García n. sp.

Figs. 1 and 2

Derivation of name. The specific epithet rugosus is from the Latin of “wrinkled”, referring to the dorsal appearance.

Holotype. CES–567, housed at the Institutional Collection from the El Soplao amber outcrop located in the laboratory of the El Soplao Cave (Cels, Cantabria, Spain). The holotype is a well-preserved specimen in a transparent amber piece, but the dorsal-ventral compression has deformed the natural disposition of some parts and made difficult the observation for some characters.

Type locality. The El Soplao site, in the municipality of Cels (Cantabria, Spain). The piece was found at the Las Peñosas Formation, Early Albian in age (Najarro et al., 2009).

Diagnosis. See generic description.
Description. Body elongate, subparallel; length 1.17 mm (as preserved); maximum body width 0.60 mm.

Antennae long, nearly reaching base of the elytron; the last three antennomeres slightly larger than the preceding ones in a very weak apical club (Fig. 2D). Antennomeres IX and X 1.2 times wider than the preceding antennomeres; antennomere XI 1.3 times longer than the antennomere X and subequal in length. Head with slight depression between eyes.

Pronotum, convex, broader than long, widest at base; maximum length 0.32 mm; maximum width 0.39 mm. Anterior border of pronotum medially produced forward and rounded; width of process 0.20 mm; anterior angles obtuse. Lateral borders of pronotum subparallel, slightly thickened, with fringe of long, erect setae (Fig. 1A). Postero-lateral angles of the pronotum acute, closely interlocking with base of elytron; posterior border of pronotum bisinuate. Discal areal of pronotum free from obvious depressions or grooves, with sparse, erect setae.

Elytral length 0.85 mm, elytral width 0.60 mm; elytra 2.6 times longer and 1.5 times wider than pronotum. Elytra convex covered with sparse, long, erect setae; lateral elytral border thickened, with a fringe of long, erect setae, as on pronotum (Fig. 2B); elytral apices rounded; elytral borders weakly serrate near apex. Strial punctures on disk deep and rounded, one third as broad as intervals. Elytral intervals highly sclerotized and slightly convex near base.

Remarks and comparative notes. A suite of shared characters allows us to confidently place this specimen in the beetle family Elmidae. The combination of long, slender antennae widely inserted, large, protuberant eyes, a pentagonal scutellum that is abruptly elevated anteriorly, long legs with long, simple tarsi, a 5–5–5 tarsal formula, metacoxae with a posterior face, pronotum with complete lateral carinae, the last tarsomere longer than the other four combined, large tarsal claws, and five abdominal ventrites place this species within Elmidae. The family is divided in two subfamilies, and due to the very small size (1.17 mm in length), the head slightly retracted into the prothorax (the “turtle-neck”), the filiform antennae, long tarsi and tibiae, globose procoxae, long prosternum, and the general habitus of pronotum, E. rugosus n. gen. n. sp. may fits correctly into Elminae. However, some inconsistent characters are found and the subfamily remains incertae sedis (see below).

This specimen lacks a visible plastron of modified setae, a character shared by all extant Elminae. The lack of a visible plastron does not exclude this specimen from Elminae, though, as even on recently collected specimens the plastron is often nearly impossible to discern if the specimen is submerged in liquid, and the preservation in amber looks remote from dry conditions. Additionally, E. rugosus n. gen. n. sp. possesses a unique character: a thickened edge of the pronotum and elytra, where a series of long, erect setae are inserted (Figs. 1A, 2B). No specimens, extant or extinct, with this diagnostic character have ever been described within the family. Only a few genera of Elminae have elytral setae, e.g., Macronevia Jäch et Boukal or Zaitzeviaria Nomura, but none are as long and conspicuous as the dorsal setae of E. rugosus n. gen. n. sp. Long dorsal setae are found in some members of the subfamily Larainae, but all Larainae have
transverse procoxae and most of them have clearly loosely clubbed antennae (Kodada and Jäch, 2005a). By contrast, *Elmadulescens* n. gen. possesses globular procoxae (though very deteriorated and compressed against each other) and filiform antennae. The basal position of this fossil in the family and its ancient age could be the cause of such an ambiguous set of characters.

Several closely related aquatic byrrhid groups have long dorsal setae. Dryopidae Bilberg, Limnichidae Ericsson, and Lutrochidae Kasap et Crowson, also have long elytral setae (Hernando and Ribera, 2005; Ide et al., 2005; Kodada and Jäch, 2005b). Dryopidae adults can be recognized by the short antennae, with most segments broader than long, and antennomeres from IV to the end forming a more or less loose club (Ide et al., 2005). *Elmadulescens* n. gen. is not Limnichidae because the head is not capable of being retracted fully into the pronotum and the dorsal surface of the body is not clearly convex (Fig. 2A) (Lawrence et al., 2000).

*E. rugosus* n. gen. n. sp. does not resemble any extant palaearctic genera of Elmidae. It is similar in size to and possesses sublateral pronotal carinariae like *Ouliminius* Gozis, but the long elytral setae distinguish it from this genus. Among other non-Palaearctic genera, it seems most closely allied to an informal group of Neotropical Elmidae composed of *Hintonelmis* Spangler, *Hexacyclops* Hinton, *Neolimnius* Hinton, *Pilieimus* Hinton, and *Tyletelmis* Hinton, based on the prominent eyes, which have a strong depression between them. It does, however, differ significantly from either of these genera in body form, size, and degree of carination on the pronotum.

5. Discussion

Members of the subfamily Elmidae are typically found in the benthos of streams and rivers, though they can be found in a variety of other aquatic habitats, including seeps and springs, as well as at the margins of lakes and ponds (subfamily Elminae); or above the water line in the splash zone, on downstream surfaces of rocks, logs, and branches, or accumulated in leaf packs (subfamily Larainae) (Jäch and Balke, 2008; Kodada and Jäch, 2005a; Maier, 2012). Despite their close association with aquatic environments, the fossil record for Elmidae, and Byrrhoidea in general, is sparse. Their small size and affinity to fast-flowing water makes them unlikely to be preserved into compression fossils.

*E. rugosus* n. gen. n. sp. is the oldest recorded fossil for the family and the only elmid fossil recorded since *P. samlandica* was described from Eocene Baltic amber (Bollow, 1940; Kirejshuk and Ponomarenko, 2014), because *Potamophilites* Haupt, recorded as an elmid by Kirejshuk and Ponomarenko (2014), is actually a dryopid (Haupt, 1956). The family’s aquatic habit is probably the main cause for their scarcity in amber fossils; they seem unlikely candidates for preservation in tree resins taking into account the chemical hydrophobic character of the resin and the behaviour of these beetles. It is not impossible, though, that an aquatic beetle could be found in amber as it takes its brief maiden flight after pupation (Seagle, 1980; Wichard et al., 2009). Based on the wrinkled dorsal surface of the fossil, it is possible that *E. rugosus* n. gen. n. sp. was a teneral specimen, one not yet firmly sclerotized after pupation. This specimen was probably trapped on a resin flow while it was searching for aquatic habitat, but the finding of the specimen embedded in amber with the wings folded may indicate that this specimen was not trapped in flight or pulled by the wind. The discovery of recent elmids of the subfamily Larainae above the water line increases the possibility that a specimen of this family could be found embedded in fossil resin while associated with a rock or wood surface near water.

The plastron, a very thin layer of air held by a dense coating of water-repellent cuticular structures, acts as a physical gill so that adults do not need to come to the surface for respiration (Hinton, 1976; Spangler and Perkins, 1989). The strategy occurs in diverse aquatic coleopteran lineages and there is evidence suggesting that this structure evolved several times within the order, as it is found in some members of Hydrophilidae Latreille, Dryopidae, Elmidae, and Curculionidae Latreille (Schowalter, 2009). The plastron is often difficult to discern in extant specimens and can be easily overlooked in the descriptions. Nonetheless, *E. rugosus* n. gen. n. sp. shows a thickened edge of the pronotum and elytra with a series of long, erect setae, that may have been related or work together with plastron respiration. In addition, the dorsal surface of the prothorax and elytra are covered with sparse, long, erect setae, which resembles that of some aquatic and riparian genera of Dryopidae and other elmids, may have entrapped air for underwater respiration and for prevention of wetting of the body (Kodada and Jäch, 2005a, 2005b).

On the other hand, *E. rugosus* n. gen. n. sp. exhibits other morphological adaptations to their unusual habitat. The very strongly sclerotized cuticle, and retractable head into the prothorax, are also features to minimize injury if the beetles become dislodged in strong current; the legs are long and tarsal claws are very large and stout, which enables them to cling firmly to substrate (Kodada and Jäch, 2005a). Their small size enables elmids to seek refuge in interstices, although small size may not have evolved as an adaptation directly related to a life in fast-flowing water, but as a an adaptation related to plastron respiration (Ward, 1992). Indeed, elmids are smaller than most aquatic coleopterans. This entire suite of characters suggests that *E. rugosus* n. gen. n. sp. was adapted to life in rapids, as with other members of Elminae, although it is speculative.

The absence of the family from other published lists of Coleoptera in amber and from other descriptions of Cretaceous fossil beetles (Grimaldi et al., 2000; Penney, 2010 and references herein; Poinar, 1992; Poinar and Milki, 2001; Skidmore, 1999) makes this specimen both unique and valuable.

6. Conclusions

One new genus and species of Elmidae is described based on a single fossil specimen from Early Cretaceous amber of Spain, in the El Soplao deposit. *E. rugosus* n. gen. n. sp. is the oldest member of Elmidae, and suggests the possible pre-Cretaceous origin for the family, indicating that elmids existed already at 110 Ma, and the adaptability of the Byrrhoidea to aquatic environments since the
Cretaceous. Additionally, it is the only aquatic beetle found in any Mesozoic amber locality, probably because fossilization of aquatic specimens in tree resin is rare.

Acknowledgements

We thank Rafael López-del Valle (Museo de Ciencias Naturales de Álava, Spain) the preparation of the Spanish sample and to the management team of the El Soplao Cave (Cantabria, Spain) the loan of the specimen. We are also grateful to Michael Engel (Natural History Museum and University of Kansas, Kansas) for providing support to this investigation, hosting DP at the University of Kansas. Thanks also to Ignacio Ribera (Institut de Biologia Evolutiva (CSIC-UPF), Spain) for the ideas about the placement of the specimen, to Matthew Gimmel (University of Kansas, Kansas) for helpful comments and input, to Vincent Perrichot (University of Rennes-1, France) for the French translations along the manuscript, and to anonymous reviewers for their useful criticisms and corrections. This work is part of the Ph.D. dissertations of DP and AS-G, supported by grants from the Spanish Ministry of Education, Culture and Sports and Spanish Ministry of Economy and Competitiveness, respectively. This is a contribution to the project CGL2011–23948, named “The Cretaceous amber of Spain: A multidisciplinary study II”, from the Spanish Ministry of Economy and Competitiveness. This research was also supported by US National Science Foundation grant #DEB–0816904 to Andrew Short and the RU Entomology Endowment Summer Scholarship to CAM.
